

Their conclusion survives running their own simulation at the persistence level their data implies

Their deposited simulation run unmodified (doi:10.6084/m9.figshare.31389142, CC BY 4.0) at 12.5 µg/mL over 12 days, with min_bR = 2 as recorded in their own output. 40 populations per low-persistence arm, 20 per high-persistence arm. A and B use the basis their own Fig_3_a-b.R plots, which filters to final MIC > 2. Raising the low-persistence level nineteen-fold does not change its outcome (Mann-Whitney p = 0.45); the contrast widens slightly rather than closing. The high-persistence value is pinned at 1 because the observed survival exceeds what the model can produce at any persistence level. Alpha is not identifiable from survival data, so these are values consistent with the observed survival, not estimates.
